HIGH BRIGHTNESS ELECTRON BEAMS
FROM PLASMA-BASED ACCELERATION∗

Abstract

Plasma Wakefield acceleration is a promising new acceleration technique that profits by a charged bunch, e.g. an electron bunch, to break the neutrality of a plasma channel to produce a wake where a trailing bunch (or witness) is eventually accelerated. The quest to achieve extreme gradient conserving high brightness has prompted to a variety of new approaches and techniques. Most of the proposed schemes are however limited to the only plasma channel, assuming in the vast majority of cases, ideal scenarios (e.g. ideal bi-gaussian bunches and uniform density plasma channels). Realistic start-to-end simulations, from the photo-cathode to FEL via a high gradient, emittance and energy spread preserving plasma section, are mandatory for paving the way towards plasma-based user facilities.

INTRODUCTION

Plasma-based accelerators (PBAs) represent, today, a new frontier for the development of compact advanced radiation sources and next generation linear colliders. High brightness electron beams are the future goal of such kind of accelerators, a new technology that is envisioned to compete with the RF technology. Since the very first conception [1] great effort (with equivalent progress) has been placed [2–8] to demonstrate the acceleration of electron beams with gradients of the order of several tens of GV/m, produced either by a laser drive (LWFA) or with a particle driven (PWFA). In PWFA the high gradient wakefield is induced by a high-energy charged particle beam (referred to as driver bunch) travelling through a pre-ionised plasma. The background electrons by shielding the charge breakup produced by the driver induce an accelerating field. The second bunch (referred to as trailing bunch or witness) placed on the right phase is so accelerated by the induced electric field [9–11].

The aforementioned publications indicate that either LWFA and PWFA are capable to produce strong accelerating gradients, but do not address the issue of beam acceleration with quality retention. In other words, the capability for a PWFA scheme to accelerate a trailing bunch with an acceptable quality for any scientific applications, such a Free Electron Laser (FEL) or a future particle–particle collider, or even for medical applications is still an open question.

The work presented in this proceeding tries to address the problem of quality bunch transport numerically for a PWFA scheme. The scheme proposed leverages on the well establish RF know-how to produce and manipulate the bunches to match the strict plasma matching requirements, so that, once injected into the plasma the trailing bunch is boosted to the desired energy. The scheme can thus be decoupled into two parts. A first stage aims in generating two electron bunches (the driver and the trailing bunch) with a given time-separation so that once injected into the plasma they will be at right phase to maximize acceleration. The generation, distance positioning and acceleration is achieved using the COMB [12] technique and an RF in the X-band regime, for a final particle energy of 500 MeV. The plasma with a $10^{16}$ cm$^{-3}$ number density is confined by a millimeter diameter capillary and ionized with plasma discharges, accelerates the particles from 500 MeV to 1 GeV in about 30 cm. The particle extracted from the plasma accelerating section are then injecting into a FEL. The evolution of the beam, from the photo-injector to the FEL via the plasma cell, is performed with a single simulation by concatenating several codes used to addressed the different physics occurring in the different accelerating section. We refer to this single simulation as a start-to-end simulation. This work is part of EuPRAXIA [13, 14] (European Plasma Research Accelerator with eXcellence In Applications) European project whose final goal is to use PBA to seed a FEL for physical and biological applications. Specifically EuPRAXIA@SPARC_LAB [14] is the envisioned EuPRAXIA European Italian-located facility operating at 1-5 GeV for FEL experiments.

INJECTOR

A comb-like configuration for the electron beam is used to generate simultaneously a 200 pC driver followed by a 30 pC trailing bunch. The comb-like operation foresees the generation of two or more bunches within the same RF accelerating bucket through the so-called laser-comb technique [12, 15] consisting in a train of laser time-spaced pulses illuminating the photocathode. The witness arrives earlier than the driver on the photocathode and then they are reversed in time at the end of the velocity bunching process, during which the longitudinal phase space is rotated. Experimental results have been obtained at SPARC_LAB where the laser-comb technique is routinely used in order to produce trains of multiple electron bunches [16] for narrow-band

THz generation [17], two-color FEL experiments [18, 19] and resonant particle driven PWFA [20]. Computational studies have been dedicated to provide two bunches separated by 0.55 ps [21], which corresponds to $\lambda_p/2$, being the plasma wavelength $\lambda_p = 330 \mu m$ given $n_p = 10^{16} \text{cm}^{-3}$. Both driver and witness bunches must be compressed down to $\sim 50 \text{fs}$ and $10 \text{fs}$ (FWHM), respectively. The process needs some fine-tuning to avoid emittance growth, naturally occurring because of the witness-driver overlapping during the velocity bunching regime. The photocathode laser has been shaped in order to provide at the cathode a witness and a driver bunches separated by $\Delta t = 4.8 \text{ps}$. With this configuration the beam crossing occurs in the second TW accelerating cavity and a fine-tuning of the RF phases suffices to provide the desired 0.55 ps beam separation corresponding to $\lambda_p/2$. Gaussian longitudinal distribution with $\sigma_z = 120 \mu m$ (RMS) and uniform transverse distribution of radius $r = 0.35 \text{mm}$ have been assumed for the witness pulse at the cathode. The different intensities between the two pulses permit to generate bunches with different charges: a 30 pC trailing bunch and a 200 pC driver. It is worth to notice by adopting a $\sigma_D = 0.35 \text{ mm}$, the FWHM witness length does not suffer lengthening, although the minimum RMS witness length is obtained for $\sigma_D = 0.25 \text{ mm}$. The sliced current at the end of the photo-injector line is plotted in Fig. 1.

LINAC

The X-band RF linac is used to accelerates the entire beam to 500 MeV [22, 23], energy of the beam entering the plasma, specifically the trailing bunch is prepared for plasma injection with a transverse dimension of $1 - 2 \mu m$ spot size. The comb-like electron beam undergoes deep over-compression in the photo-injector by means of the velocity bunching scheme. The same accelerating gradient of $E_{acc} \approx 20 - 36 \text{ MV/m}$ is applied in L1 and L2 linac section respectively, and the final electron beam energy is $E_{L2exit} \approx 580 \text{ MeV}$, with an energy spread less than 0.1%. The driver and witness bunches are characterized by high charge/low current and low charge/high current, respectively. Moreover, the initial matching conditions for the injection in the X-band linac are quite different for the two bunches, as shown by their transverse phase space at the linac entrance (i.e. injector exit). In this regard, an efficient sharing of the same lattice is achieved by means of a mild transverse focusing that aims to keep the RMS size of the comb beam compatible with the beam stay-clear-aperture through all the X-band linac. The same argument applies also to the focusing stage with the permanent quadrupoles at the entrance of the plasma capillary where a residual asymmetry between horizontal and vertical plane for the witness beams is present, see Fig. 2.

PLasma and wakefield acceleration
THE PLASMA CELL

Start-to-end simulations use, for the plasma section, the state-of-the-code ARCHITECT [24, 25]. The use of Architect has been dictated by the necessity to run long simulations where a classical particle-in-cell (PIC) approach would have been computationally too expensive. The Architect reduced model, which relies on a fluid background, has been benchmarked numerically against the ALaDyn-PWFA [26] PIC code [25] and versus SPARC_LAB experimental results [27, 28]. Start-to-end simulations are performed by concatenating the use of codes without any phase space manipulation or remapping. Specifically, for the interface RF X-band with plasma The ELEGANT code is used to track particle up to the plasma entrance, the particle phase-space is then imported into the Architect code for the evolution in the plasma section. Simulations described in this section have been run with a longitudinal resolution of 1 µm and a transverse resolution of 0.4 µm, a mesh that allows to resolve the fine structure with a reasonable computational cost. The advancing time step is of 1.1 fs. The number of particle used to discretize the driver is, on average, 30 particles per cell while the witness is discretized with an average of 100 particle per cell. We recall that the goal is to accelerate the trailing bunch retaining as much as possible its original quality. To limit the energy spread growth, the trailing bunch has been designed with a (as much as possible) triangular shape. The triangular shape together with a specific value of peak charge represents the optimized longitudinal density profile that limits energy growth spread during propagation. Driver and witness have been designed to perform the best acceleration in terms of quality and in terms of energy transfer (transformer ratio, R) [29], parameter that identifies the rate of energy transfer from the driver to the witness. In our case the transformer ratio in estimated in the range 2-3. The foreseen experiment is planned in the so-called weakly-non-linear regime, where despite fields resemble a sawtooth profile linear field sum is still possible. The parameter we used to measure the degree of nonlinearity is the reduced charge parameter [30, 31], \( Q = \frac{N_b}{n_0} \frac{\lambda_p}{\lambda_b} \), with \( N_b \) the electron bunch number (bunch charge divided by the elementary charge). For this case the driver reduced charge is \( Q \sim 0.8 \sim 0.9 \).

Nonetheless, if the upstream application is a FEL application that requires a slice current around 2 kA, combining this requirement with the triangular shape, simulations helps identifying that beam loading compensation occurs for a driver-witness distance 184 µm or \( 0.55 \times \lambda_p (n_0 = 10^{16}) \), where the electric field experienced by the witness is around 1.1 GV/m.

We recall that the accelerating field together with the plasma wavelength depend upon the plasma number density \( n_0 \propto n_{1/2} \) and \( \propto n_{-1/2} \) respectively. The capability to control the density would permit some flexibility and adjustments in the bubble profile and accelerating fields, this to compensate -on site- whenever the distance between driver and witness would oscillate or change for experimental unforeseen reasons. The flat density profile, together with the required value is achieved with a capillary tube. The capillary tube, confining the ejected gas, permits a high degree of control to which we can rely on for experimental on site optimization. At present simulations consider some density ramps of the order of 0.5 cm, that are experimentally reasonable and whose length is below the betatron wavelength assuring no bunch oscillations within the ramps to increase acceleration robustness [26]. At plasma entrance, the trailing bunch is delivered with a shape that resemble the triangular required shape, transversally the bunch is fairly symmetric in size and in emittance Table 1. The driver is instead of lower brightness quality, but since the driver will undergo depletion -anyway- we can accept a lower quality since its main purpose is to only drive the wake. The setting of the RF line in favor of the witness naturally bring the driver on a less optimized point that is delivered at plasma with a lower quality than the trailing bunch. The driver at plasma entrance has the front part that is highly convergent, convergence that in favor of the witness naturally bring the driver on a less robustness [26]. At plasma entrance, the trailing bunch is dilution, while the central slice with very high current retains high quality. The witness, at plasma entrance, has the emittance in both planes as well as the energy spread almost uniform along the entire witness length. After the plasma acceleration section, the bunch has lost this homogeneity exhibiting a different slice quality along its length.

The front part and the read part of the witness are characterized by large emittance and energy spread. While ideally

Table 1: PWFA bunch parameters at plasma entrance and at plasma exit. The best slice value is also reported.
The electron beam accelerated by plasma are then transported to an undulator and photon production is studied with the use of the GENESIS [32] code. Considering a $a_w = 0.8$, the resonant wavelength is $\lambda = 2.987$ nm. The matching to the undulator leads to $\sigma_x = 40.6 \mu$m and $\sigma_y = 28.6 \mu$m with the quadrupoles 9 cm long and set at 18 T/m. The FEL parameter results to be $\rho = 2.51 \times 10^{-3}$, its 3D value is $\rho_{3D} = 1.86 \times 10^{-3}$ for $L_{g,3D} = 0.37$ m. Simulations predicts The growth of the radiation, as given by simulations with GENESIS 1.3 [32], is shown in Fig. 5. The saturation length is about 15–25 m with emitted energy $6.5 \mu$J at 30 m, for a photon flux of $9.76 \times 10^{10}$ per shot. The minimum bandwidth value, achieved at 20 m is 0.3%, while at 30 m saturation effects have increased it to 0.9%. Finally, the nominal case a1 has been worsened in current, emittance and energy spread by 5% and 10%, we observe a decrease in the emission respectively of 8% and 13%.
